# Advanced UNIX Programming

**Processes, threads, concurrency, signals**

**networking, non-blocking & async I/O**

**hw3-multi-server:**

add complex functionality to a provided basic web server

# Crossing to the Kernel: System Calls

Sometimes a process needs to perform privileged operations, e.g.:

- File I/O: `open()`, `read()`, `write()`, `close()`, etc.
- Memory management: Allocate/free memory, protection
- Process management: `fork()`, `exec()`, etc.

Can't trust (nor expect) userspace processes to do bookkeeping & access control.

**OS needs to provide a well-defined interface to the kernel!**

**hw4-tabletop:**

add a new system call to Linux and install custom kernel to test it

inspect a running process's file descriptor table

# Synchronization

Many threads of execution can concurrently access shared memory.

Race conditions can lead to data corruption and unpredictable behavior.

**Need OS support to provide mutual exclusion and synchronization!**

**hw5-fridge:**

- implement an in-kernel hashtable accessible via system calls

- use synchronization primitives to ensure safe data structure access

# Scheduling

System may have many processes to execute, but fixed # of CPUs...

**OS needs to virtualize the CPU! (i.e. provide illusion of infinite CPUs):**

- multiplex process execution across multiple CPUs
- permit higher priority processes to run sooner/for longer

**hw6-freezer:**

add a new scheduling policy to the Linux scheduler

replace the default Linux scheduling policy

# Memory Management

Processes execute within a **byte-addressable linear virtual address space**

*Perks: pointers, arrays, stack grows “downwards”, heap grows “upwards”*

How is this possible given fixed RAM size and variable # of running processes?

**OS needs to virtualize physical memory (i.e. provide illusion of linear vaddr spaces)**

- map virtual addresses to physical addresses on-the-fly
- protect virtual memory mappings from other processes and illegal access

**hw7-farfetchd:**

“hack” a process’s address space by writing directly to its physical memory

# File Systems

File access is made straightforward by the file API (syscalls), but there are many implementation details hidden behind the kernel:

- read/write/execute permission enforcement, user access validation
- resolving path names and fetching corresponding data at offset from disk
- persisting metadata and data on disk, keeping metadata synchronized

**The OS needs to implement the file API and ensure data persistence**

**hw8-ezfs :**

implement a simple file system and hook it into Linux VFS

# Stuff we skimmed/missed

Deadlock theory

I/O systems

Network file system (NFS)

Interrupt handlers and bottom half

Kernel synchronization using RCU

Kernel memory management & block I/O layer

Virtualization

Networking

# Final

2-hour long - 50% longer than the midterm

Double-sided cheat sheet

Will focus more on the second part of the course:

- Scheduling - HW6
- Memory Management - HW7
- File System

**However, you will need concepts from throughout the course, e.g., locks**

# Final Reminders

Fill out Courseworks evaluation (!!!)

Remember your pledge

- Don't share class materials with friends
- Don't post any class-related code to GitHub
- Don't post any class materials to Chegg, CourseHero, etc

If you enjoyed OS, consider taking COMS E6998

**Topics in Cloud Computing** next fall
